Preface

This is the reader for the course “Duality Theory: Connecting Logic, Algebra, and Topology” given during the winter semester 2023/24 at *LMU Munich* as part of the *Master in Logic and Philosophy of Science*. The reader is written as the course progresses. A website (or rather git repository) with all the course material is found at

<https://github.com/LevinHornischer/DualityTheory>.

Comments I’m happy about any comments: spotting typos, finding mistakes, pointing out confusing parts, or simply questions triggered by the material. Just send an informal email to Levin.Hornischer@lmu.de.

Course description and objectives This course is an introduction to duality theory, which is an exciting area of logic and neighboring subjects like math and computer science. The fundamental theorem is Stone’s duality theorem stating that certain algebras (Boolean algebras) are in a precise sense equivalent to certain topological spaces (totally disconnected compact Hausdorff spaces). This has been extended in many ways. The underlying idea is that the two seemingly different perspectives—the algebraic one and the spatial one—are really two sides of the same coin:

- formulas/propositions vs. models/possible worlds,
- open sets of a space vs. points of the space,
- properties of a computational process vs. denotation of the computational process.

In terms of content, the focus of the course will be to introduce the mathematical theory. In terms of skills, the aim is to learn how to apply the tools of duality theory. We will illustrate this with applications that make use of dualities by combining the often opposing advantages of the two perspectives.

Prerequisites An introductory course in logic and some familiarity with mathematics (ideally, but not necessarily, having seen elementary concepts

of topology and algebra), including the basics of writing mathematical proofs.

Apart from that, the course can be taken independently. But it also makes sense to take it as a follow-up course of the course “Philosophical Logic”, which I taught in the summer semester 2023. In that course, I stressed two different approaches to giving semantics to various logics: the algebraic approach and the state-based approach. We’ve seen that these semantic approaches are often equivalent, and this is a special case of the more general phenomenon of duality.

Contents We start with an informal chapter describing the key idea of duality. The rest of the course is about developing this key idea precisely. For this, we follow the recent textbook Gehrke and van Gool 2023. We first precisely define the algebraic structure (lattices) and then topological structures (topological spaces), and we finally prove the duality result. The remainder of the course is about deepening this result and applying it in logic and computer science.

Layout These notes are informal and partially still under construction. For example, there are margin notes to convey more casual comments that you’d rather find in a lecture but usually not in a book. Todo notes indicate, well, that something needs to be done. References are found at the end.

This is a margin note.

This is a todo note

Study material The main textbook that we use is by Gehrke and van Gool (2023). And informal introduction to duality is provided by Gehrke (2009). Some further textbooks include:

- R. Balbes and P. Dwinger (1975). *Distributive lattices*. University of Missouri Press
- B. A. Davey and H. A. Priestley (2002). *Introduction to Lattices and Order*. 2nd ed. Cambridge: Cambridge University Press

Notation Throughout, 'iff' abbreviates 'if and only if'.

1 Introduction: the key idea of duality

Duality theory is a mathematical theory relating algebraic structures to geometric or spatial structures. It is a formal mathematical theory; but underlying it, is a deep philosophical idea. In this chapter, we describe this philosophical story—the key idea of duality—before developing the mathematical theory and its applications in the later chapters.

Advice on how to read this chapter Duality theory can be confusing when one first hears about it. One has to keep track of many moving parts, going in different directions, making sure they all fit together. At least to me, reminding myself of the philosophical story helps: it provides the ‘rhyme and reason’ to the mathematics. So whenever you feel lost in the midst of the technical detail, you can come back to this philosophical story. It is a powerful and potentially unfamiliar idea, so give it some time to sink in and go through this conceptual motivation over and over again. Also, as you progress to the later, more technical chapters, be sure to come back to this introduction chapter to see how the intuitive ideas here are developed formally.

Duality theory can be quite abstract. The advantage of this is that it makes duality ubiquitous and widely applicable. But a disadvantage is that this makes it less accessible. So before attempting any general definition of duality, let us consider several examples (section 1.1). From those we can generalize an informal characterization of duality (section 1.2). This then hints at how duality theory is formalized mathematically and how it can be applied. Finally, in section 1.3 we list some exercises.

1.1 Intuitive examples of duality

We present several examples of duality. We do so at a very informal and intuitive level, and we do not at all aim to be philosophically careful or mathematically precise. In fact, think of it as an *exercise* to revisit these examples once you know more about the formal development of duality theory—and see what more precise analysis you can provide.

For other expositions of the philosophical idea behind duality, see, e.g., Abramsky (1991), Gehrke (2009), and Vickers (1989).

To use the words of Abramsky (2023).

I think this is a philosophically very fruitful exercise—or, better, research project. In particular, this makes for an excellent essay topic.

Metaphysics: Properties vs objects When we perceive and reason about the world, we naturally think in terms of there being various objects that have—or do not have—various properties. Objects are, for example, my laptop, the Eiffel Tower, or the Moon. Properties are, for example, being red, being higher than 300m, or being made of cheese. (We consider here only unary properties: i.e., those that apply to a single object, but not to multiple objects, like being taller than.) Let us write \mathcal{O} for the set of all objects and \mathcal{P} for the set of all properties. Crucially, observe that there is a certain dependency between \mathcal{O} and \mathcal{P} :

$(\mathcal{O} \rightarrow \overline{\mathcal{P}})$ Each object $x \in \mathcal{O}$ determines a set of properties $F_x \subseteq \mathcal{P}$ consisting of precisely those properties that x has.

(The bar in ' $\overline{\mathcal{P}}$ ' indicates that we assign to each x a *set* of elements in \mathcal{P} rather than a single element of \mathcal{P} .) So we might wonder whether we can also go in the opposite direction ($\overline{\mathcal{P}} \rightarrow \mathcal{O}$)? Does a subset F of properties also determine an object, i.e., the unique object that has exactly the properties in F ? Actually, no: some sets of properties might not be satisfied by any object (e.g., $F = \{\text{being exactly 300m high, being exactly 200m high}\}$) or by more than one (e.g., $F = \{\text{being exactly 300m high}\}$).

But let us not give up too early. After all, the set F_x is not just *any* set of properties, but it has some nice features which we collect now. (And the hope is that if F is a set of properties with these nice features, that then it determines a unique object.)

1. Assume $a, b \in \mathcal{P}$ are two properties such that having a implies having b ; we abbreviate this as $a \leq b$. For example,

$$a = \text{being higher than 300m} \leq \text{being higher than 200m} = b.$$

So if our object x has property a , then it also has property b , i.e., if $a \in F_x$, then $b \in F_x$. We may express this as: F_x is closed under implication.

2. Assume $a, b \in \mathcal{P}$ are two properties. Note that then there is another property: namely, the property of having both property a and property b . We denote this property $a \wedge b$. So $a \wedge b$ is again in \mathcal{P} and we have $a \wedge b \leq a$ and $a \wedge b \leq b$. Moreover, if our object x has property a and it has property b , then it has property $a \wedge b$, i.e., if $a, b \in F_x$, then $a \wedge b \in F_x$. We may express this as: F_x is closed under conjunction.

Philosophers know phrases of the form 'The F' (referring to the unique object satisfying F) as definite description. For their important role in philosophy, see e.g. Ludlow (2022).

Later we will say F_x is an upset. This sounds funny now, but by the end of the course, you will have said this so often that you won't even notice.

3. Similarly, if $a, b \in \mathcal{P}$ are two properties, there also is the property of having either property a or property b (or both). We denote this property $a \vee b$. So $a \vee b$ is again in \mathcal{P} and we have $a \leq a \vee b$ and $b \leq a \vee b$. Moreover, if our object x has property $a \vee b$, then either it has property a or it has property b , i.e., if $a \vee b \in F_x$, then either $a \in F_x$ or $b \in F_x$. Later, we express this as F_x being prime.
4. Note that \mathcal{P} also contains the trivial property like being identical to oneself. We denote this property \top . In particular, our object x has it, i.e., $\top \in F_x$.
5. Similarly, note that \mathcal{P} also contains the inconsistent property like not being identical to oneself. We denote this property \perp . In particular, our object x does not have it, i.e., $\perp \notin F_x$.

Now, we can ask our question again: If F is a set of properties with these features, does *it*—as opposed to any arbitrary set of properties—determine a unique object? In other words, is there exactly one object that has all the properties in F ? It might be an attractive metaphysical (or, better, ontological) principle to answer yes and hold that:

$(\overline{\mathcal{P}} \rightarrow \mathcal{O})$ Each set of properties $F \subseteq \mathcal{P}$ satisfying (1)–(5) determines an object $x \in \mathcal{O}$, namely, the unique object having exactly the properties in F .

The uniqueness part is close to Leibniz's principle about the **identity of indiscernibles**: if two objects x and x' have exactly the properties in F , they are indiscernible, and hence are identical according to Leibniz. The existence part amounts to a certain *ontological completeness*: that for every consistent description F of an object, there in fact is a (possible) object that has these properties. For this, we should consider \mathcal{O} to contain not only the objects in our world, but all possible objects. After all, the actual world need not be ontologically complete: F might consistently describe a unicorn, even if this does not exist in the actual world.

We will see that this bidirectional determination ($\mathcal{O} \rightarrow \overline{\mathcal{P}}$) and $(\overline{\mathcal{P}} \rightarrow \mathcal{O})$ is a hallmark of duality, here between objects and properties. We might also speak of mutual dependency, supervenience, or necessitation.

Moreover, we started our considerations from objects and considered their ontology; but we could also start from properties and wonder about their ontology. The analog of Leibniz's principle would be the extensional-ity principle: two properties a and b are identical if they apply to exactly

*I will always read 'either A or B' as inclusive-or (either only A is the case, or only B is the case, or both A and B are the case) Cf. a number $p > 1$ is prime iff (that is **Euclid's lemma**), for all numbers a and b , if $a \times b$ is divided by p , then either a is divided by p or b is divided by p).*

Or is the list (1)–(5) not complete because we should also add a principle concerning negation: you can think about this in exercise 1.b.

Actually, I don't know if a principle like this is considered in metaphysics: if you do, please let me know :-). Also see exercise 1.c asking for a comparison to formal concept analysis.

Cf. the extensionality principle in set theory which says that two sets are identical iff they have the same elements.

the same possible objects (i.e., for all $x \in \mathcal{O}$, x has a iff x has b). Each property a determines a set of objects: namely, the set of those objects that have property a . This is known as the *extension* of the property. Analogously to before, we might also ask if every set of objects determines a property: namely, the property determined by having this set of objects as extension. Prima facie one would think that this should be the case, but we will see that duality provides a different answer: only some—and not all—sets of objects determine a property.

Since we talk about all possible objects, not just the actual ones, some philosophers might rather call this the intension of the property, as it involves not just the actual world, but also objects from other possible worlds.

Semantics: Propositions vs possible worlds The central question of philosophy of language is: What is the meaning of sentences? The meaning of a sentence is also called the *proposition* that the sentence expresses. The standard answer to this question, as far as there is one, is possible worlds semantics: The meaning of a sentence (i.e., the proposition it expresses) is the set of possible worlds in which the sentence is true. Here, a possible world is a consistent and complete description of how our world could have been. One example is the possible world which is just like our world but where the Eiffel Tower is 400m high. So the proposition a expressed by the sentence ‘The Eiffel Tower is 330m high’ contains the actual world x_0 (i.e., $x_0 \in a$) but not the just described possible world x_1 (i.e., $x_1 \notin a$). Some common notation for the phrase ‘world x makes true proposition a ’ is $x \models a$; so possible world semantics analyses \models as elementhood \in .

There is much debate in philosophy what the set \mathcal{W} of possible worlds is (Menzel 2021) and what the set \mathcal{P} of propositions is (McGrath and Frank 2023). Both are taken to exist in their own right and be important objects of study. But their nature is disputed. For example, is it really the case, as possible world semantics claims, that propositions are just sets of worlds (‘worlds first, propositions later’)? Or is it rather that worlds are maximally consistent sets of propositions (‘propositions first, worlds later’)? The latter goes by the name ‘ersatzism’ since full-blown possible worlds are substituted by something constructed out of linguistic entities—and ‘Ersatz’ is German for substitute.

We won’t enter this debate here. Instead, we observe again that there is a bidirectional determination between worlds and propositions. To start, a plausible principle to hold about worlds and propositions is the following. It is satisfied by possible worlds semantics, and, in fact, arguably its characteristic feature.

World individuation Possible worlds are individuated by the propositions they make true: if two possible worlds x and y make true exactly the

Cf. Leibniz’s above principle about the identity of indiscernibles.

same propositions (i.e., for every proposition a , we have $x \models a$ iff $y \models a$), then $x = y$.

Proposition individuation Propositions are individuated by the possible worlds at which they are true: if two propositions a and b are true at exactly the same possible worlds (i.e., for every possible world x , we have $x \models a$ iff $x \models b$), then $a = b$.

A hyperintensional account of propositions would contest this; see Berto and Nolan (2021).

And there is more. Just like properties, also the set of propositions has logical structure: If a and b are propositions, there also are the propositions $a \wedge b$ (conjunction), $a \vee b$ (disjunction), $\neg a$ (negation), \top (logical truth), and \perp (logical falsity). With this we can also express implications between propositions: proposition a implies proposition b , written $a \leq b$, precisely if $a \wedge b = a$. The proposition expressed by ‘I am in Munich’ implies the proposition expressed by ‘I am in Germany’ because the sentence ‘I am in Munich and I am in Germany’ is equivalent to the sentence ‘I am in Munich’, i.e., they express identical propositions.

Thus, given a possible world $x \in \mathcal{W}$, we can again consider the set of propositions $F_x \subseteq \mathcal{P}$ that are true in x (i.e., $F_x = \{a \in \mathcal{P} : x \models a\}$). And F_x again satisfies the features (1)–(5) above: If $a \in F_x$, i.e., $x \models a$, and a implies b , i.e., $a \leq b$, then $x \models b$, i.e., $b \in F_x$. If $a, b \in F_x$, then x makes true both a and b , so $a \wedge b \in F_x$. As an exercise, go through the other cases as well.

Another plausible principle to hold about worlds and propositions is, again, that

Metaphysical completeness Each set of propositions $F \subseteq \mathcal{P}$ satisfying (1)–(5) determines a possible world $x \in \mathcal{W}$, namely, the unique possible world making true exactly the propositions in F .

Ersatzism, for example, endorses this principle; let us see why. We will later formally show that a set of propositions F satisfying (1)–(5) is maximally consistent: one cannot add a single more proposition to F without making it inconsistent (i.e., making it contain \perp). Ersatzism not only claims that then there is a world x which makes true exactly the propositions in F , it even identifies this world x with F . The metaphysical completeness claim only follows along with the existence claim, and the uniqueness of x follows from the world individuation principle above.

This is assuming that the set of propositions forms what is known as a Boolean algebra.

In other words, there is an exact match between possible worlds and sets of propositions satisfying (1)–(5). Formally, we say there is a bijective correspondence between the set \mathcal{W} of possible worlds and the set $\overline{\mathcal{P}}$ of sets

of propositions satisfying (1)–(5). (To anticipate terminology, these sets $F \in \overline{\mathcal{P}}$ will be called *prime filters* and $\overline{\mathcal{P}}$ will be called the *spectrum* of the algebra of propositions.)

$$\mathcal{W} \xrightarrow{\sim} \overline{\mathcal{P}}$$

$$x \mapsto F_x = \{a \in \mathcal{P} : x \models a\}$$

the x making true exactly the $a \in F \leftrightarrow F$

Let us verify that this really is a bijection: We have already checked that the function $f : \mathcal{W} \rightarrow \overline{\mathcal{P}}$ mapping x to F_x is well-defined. It is injective by the world individuation principle: if $x \neq y$, then there is a proposition a with $x \models a$ and $y \not\models a$ (or vice versa), so $a \in F_x$ and $a \notin F_y$ (or vice versa), so $F_x \neq F_y$. It is surjective by metaphysical completeness: Given $F \in \overline{\mathcal{P}}$, let x be the unique world in \mathcal{W} making true exactly the propositions in F . Then $F = F_x$ because: $a \in F$ iff $x \models a$ iff $a \in F_x$.

So far, we have looked at the relation between full-blown metaphysical worlds (the elements of \mathcal{W}) and their ersatz constructions as sets of propositions (the elements of $\overline{\mathcal{P}}$). But what about the other side: How do full-blown propositions (the elements of \mathcal{P}) relate to sets of worlds, i.e., their counterparts propagated by possible worlds semantics?

Every proposition $a \in \mathcal{P}$ determines the set of worlds $\llbracket a \rrbracket := \{x \in \mathcal{W} : x \models a\}$ where a is true. This is also known as the *truthset* of a . And we might again wonder whether we can also go in the opposite direction: whether every set of worlds also determines a proposition? This issue is actually not too much discussed in the philosophy of a language, and one often at least talks as if this is true. So let's see where this takes us. Let us write $\overline{\mathcal{W}}$ for the sets of worlds that determine propositions and $2^{\mathcal{W}}$ for the set of all sets of worlds. So our assumption for now is that $\overline{\mathcal{W}} = 2^{\mathcal{W}}$. Analogous to the previous case, we want to know if the function

$$\llbracket \cdot \rrbracket : \mathcal{P} \rightarrow 2^{\mathcal{W}}$$

$$a \mapsto \llbracket a \rrbracket = \{x \in \mathcal{W} : x \models a\}$$

is a bijection. We are off to a good start: The function is injective by the proposition individuation principle: if $a \neq b$, there is a world x with $x \models a$ and $x \not\models b$ (or vice versa), so $\llbracket a \rrbracket \neq \llbracket b \rrbracket$. In fact, it also preserves the logical structure: $\llbracket a \wedge b \rrbracket = \llbracket a \rrbracket \cap \llbracket b \rrbracket$, $\llbracket \perp \rrbracket = \emptyset$, etc. (Later we formalize this as $\llbracket \cdot \rrbracket$ being a Boolean algebra homomorphism.) However, the issue is surjectivity. (Above, this also required another assumption: metaphysical

A function $f : X \rightarrow Y$ is injective if $x \neq y$ implies $f(x) \neq f(y)$, it is surjective if for every $y \in Y$ there is $x \in X$ with $f(x) = y$, and it is bijective if it is both injective and surjective.

If X is a set, the powerset of X is the set of all subsets of X and it is denoted 2^X or $\mathcal{P}(X)$.

completeness.)

Here is one argument why $\llbracket \cdot \rrbracket$ is not surjective. Plausibly, since propositions are the meanings of sentences, every proposition is expressed by some sentence. But since there are only countably many sentences (they are generated by a ‘finitistic’ grammar), there hence only are countably many propositions. However, since there plausibly are infinitely many possible worlds (be it countably or uncountably many), the powerset $2^{\mathcal{W}}$ of \mathcal{W} is uncountable. So \mathcal{P} and $2^{\mathcal{W}}$ have different cardinalities, which means there cannot be a bijection between, hence the already injective function $\llbracket \cdot \rrbracket$ cannot be surjective.

That is Cantor’s diagonal argument.

So actually not any set of worlds determines a proposition, i.e., $\overline{\mathcal{W}}$ is a proper subset of $2^{\mathcal{W}}$. The ingenious insight of Stone, who discovered the Stone duality, was to realize how to precisely describe this special subset $\overline{\mathcal{W}}$ of $2^{\mathcal{W}}$. The key idea is to realize that there is some additional structure on the set of worlds \mathcal{W} that we have not seen so far: a topology. But this is something that needs more introduction, and we do this properly in the formal chapters.

Also see exercise 1.d.

So we have a duality between worlds and propositions: even if we do not endorse a particular view about one side—like possible worlds semantics or ersatzism—, the duality still describes a bidirectional determination between the two. So accepting principles on one side translates to the other side, where we can use a very different set of intuitions to test the principles.

Logic: models vs formulas Logic can be done both syntactically (aka proof-theoretically) or semantically (aka model-theoretically). The completeness theorem shows that the two approaches, which are very different in spirit, actually are equivalent. This also is a form of duality. Let’s explore this concretely.

Consider the language of classical propositional logic: sentences are formed from atomic sentences p_0, p_1, \dots using the connectives \wedge, \vee, \neg and the constants \perp and \top . And consider a proof-system for classical logic: for example a Hilbert system, a natural deduction system, or a sequence calculus for classical logic. It consists of various axioms and rules to define the relation $\Gamma \vdash \varphi$, i.e., when the sentence φ is derivable in the proof-system S using as axioms the sentences in the set Γ . This is the syntactic description of the logic.

The model-theoretic description of the logic defines the relation $\Gamma \models \varphi$, i.e., that the sentence φ is a logical consequence of the sentences in Γ . This

is done as follows. A valuation is a function $v : \{p_0, p_1, \dots\} \rightarrow \{0, 1\}$ that assigns each atomic sentences a truth-value, i.e., true (1) or false (0). This can be extended to all sentences: $v(\varphi \wedge \psi) = 1$ iff $v(\varphi) = 1$ and $v(\psi) = 1$; $v(\neg\varphi) = 1$ iff $v(\varphi) = 0$; $v(\perp) = 0$; etc. Then $\Gamma \models \varphi$ is defined as: for all valuations v , if $v(\psi) = 1$ for all $\psi \in \Gamma$, then $v(\varphi) = 1$. Thus, logical consequence is truth-preservation.

Now, the completeness theorem for classical propositional logic states that: $\Gamma \vdash \varphi$ iff $\Gamma \models \varphi$. To be more precise, one often only calls the right-to-left implication ‘completeness’, and the left-to-right implication ‘soundness’. However, soundness is easy to establish. (One just needs to check, roughly, that the finitely many axioms of the proof-system are indeed logical consequences, and that the finitely many rules of the system preserves logical consequences—so the proof-system will only ever produce logical consequences.) We take soundness for granted and want to show that completeness really is a duality result.

Let us start on the syntactic side. The proof-system naturally defines a notion of equivalence between sentences: we call two sentences φ and ψ equivalent, written $\varphi \equiv \psi$, iff both $\varphi \vdash \psi$ and $\psi \vdash \varphi$. An equivalence class of a sentence φ is the set of sentences that are equivalent to it: $[\varphi] := \{\psi : \varphi \equiv \psi\}$. Write L for the set of all equivalence classes. It also has logical structure: $[\varphi] \wedge [\psi] = [\varphi \wedge \psi]$; $\neg[\varphi] = [\neg\varphi]$, etc. L is also called the *Lindenbaum–Tarski algebra* of the logic.

Now, each a valuation v determines a subset $F_v \subseteq L$: namely, those equivalence classes $[\varphi]$ with $v(\varphi) = 1$. Note again that F_v has features (1)–(5): If $[\varphi] \in F_v$ and $[\varphi] \leq [\psi]$ (i.e., $[\varphi \wedge \psi] = [\varphi]$), then $\varphi \vdash \psi$, so, by soundness, $\varphi \models \psi$, so, since $v(\varphi) = 1$, also $v(\psi) = 1$, so $[\psi] \in F_v$. If $[\varphi], [\psi] \in F_v$, then $v(\varphi) = 1$ and $v(\psi) = 1$, so $v(\varphi \wedge \psi) = 1$, so $[\varphi \wedge \psi] \in F_v$. Etc. Conversely, if $F \subseteq L$ satisfies (1)–(5), then v_F is a valuation mapping φ to 1 iff $[\varphi] \in F$. So, again, the set X of valuations is in bijective correspondence with the set \bar{L} of subsets of L satisfying (1)–(5).

But how does completeness follow? For this, first note that subsets of L are *theories*, i.e., sets of sentences (modulo provable equivalence). Now, if $\Gamma \not\vdash \varphi$, consider the deductive closure Γ' of Γ , i.e., the set of all sentences that can be derived from Γ , so also $\Gamma' \not\vdash \varphi$. When we regard Γ' as a subset of L , this is, in formal terminology, a filter of L that does not intersect the ideal of all equivalence classes that imply $[\varphi]$. Now one only needs one formal result, namely Stone’s Prime Filter Theorem (which we prove later on in the course), which says that we can extend this filter to a prime filter F which still does not intersect this ideal. Then v_F is a valuation that makes

true all the premises in Γ but not the conclusion φ , hence $\Gamma \not\models \varphi$, as desired.

Further examples in physics and computer science We sketch two further examples, one in physics and one in computer science.

Physics: states vs observations. Duality also is a central idea in physics (e.g. Strocchi 2008, p. 24). A physical system comes both with a *state space* X and an algebra A of *observations* and these two again are dual in the sense that

- the states are determined by the observations that they give rise to,
- the observations are determined by the states that give rise to them.

The observations have logical structure: in a classical (as opposed to quantum) system, observing $A \wedge B$ means observing A and observing B , observing $A \vee B$ means observing A or observing B , etc. Each state x of the system determines a set of observations: namely, those that can be made if the system is in that state. Conversely, we can also start with the algebra of observations (they are empirically more accessible anyway) and postulate the states of the system as theoretical entities corresponding to certain subsets of observations.

Computation: denotations of programs vs observable properties. Computer programs are written in a programming language, and so, much like for sentences written in a natural language, we can ask what their meaning is. The meaning of a program is called its *denotation*. For example, the denotation of a program could be the (partial) function that it computes. Domain theory is the mathematical theory to systematically describe these meanings. There again also is a side that is dual to the side of meanings, and this was a crucial discovery in the development of domain theory by Abramsky (1991, p. 16). This is the side of *observable properties* of the computer programs. For example, it could be the property that, on input $x = 3$, the program halts and outputs $f(x) = 5$. Again, we would hope for a bidirectional determination in the sense that the meaning of a program is completely determined by its observable properties, and that these observable properties are determined by the denotations that have them.

1.2 Towards characterizing duality

By now, we have an interesting stock of examples involving duality. Now it is a matter of finding a concise way to systematically describe all the

different components that are involved in a duality. We will work toward doing this formally for a good part of the course. But let's already give it an informal try here.

We had the following components in the examples:

- On the one side, we have a set X , e.g., of objects, possible worlds, models, states, or denotations. We hinted at the fact that this is not just a set, but actually a *space*, i.e., it also carries a topology.
- On the other side, we have a set A , e.g., of properties, propositions, sentences (modulo provable equivalence), observations, or observable properties. This set also has logical—or algebraic—structure: conjunction (\wedge), disjunction (\vee), logical falsity (\perp), logical truth (\top), and possibly negation (\neg).
- And we have a way to go from the spatial side to the algebraic side, and we also have a way to go in the other direction. In particular, we have:
 - A canonical way to determine from subsets of A with certain nice features an element from X , i.e., a function $\epsilon : \overline{A} \rightarrow X$.
 - A canonical way to assign to each element from A a subset of X , i.e., a function $\eta : A \rightarrow \overline{X}$.

Finally, we want the translation manual to be *formulaic* in X and A : i.e., it should not depend on the idiosyncrasies of the specific X and A ; rather, it should work for all X 's and A 's of the same kind. This is because we do not always know the exact nature of the two sides (the objects, possible worlds, etc.; resp., the properties, propositions, etc.). So we do not want the above data for specific X and A . Rather, we want it to hold for any X that is a candidate set for the spatial side, and for any A that is a candidate for the algebraic side. And hence we also want the ways of going back and forth between the two sides to respect the relations between these candidates for the spatial side and the algebraic side.

Formally, the two sides are best represented as so-called *categories*. On the spatial side, the category consists of the spatial candidates X , which are called the *objects* of the category, and their relations, which are called the *morphisms* of the category. Similarly, on the algebraic side, the category consists of the algebraic candidates A and their relations. Then we will see that all the above components of the duality is succinctly phrased as a *dual equivalence* between the spatial category and the algebraic category.

The key application of a duality is that it provides a precise back-and-forth translation between objects (or categories) of very different kinds. Thus, questions on one side translate to question on the other side where very different tools are available to solve the question.

1.3 Exercises

Exercise 1.a. Complete the left-out details in the main text. For example, why, for a possible world x the set of propositions F_x really satisfied properties (1)–(5). Similarly for valuations v .

Exercise 1.b. Right after the list of features (1)–(5), we asked in the margin if this list is lacking a principle concerning negation: If $a \in \mathcal{P}$ is a property, then there also is the property $\neg a$ of not having property a . It seems plausible to require that either a given object $x \in \mathcal{O}$ has a property or it does not. In other words, either $a \in F_x$ or $\neg a \in F_x$. Do you think this is plausible to require? What about vague properties? (Later we see that this if if we have a negation operator on our set of properties obeying the Boolean laws, than F being prime is equivalent to having the just mentioned negation property.)

Exercise 1.c (More of a research project than an exercise). Consider to what extend the first example (objects vs properties) can be developed along the lines of **formal concept analysis**.

Exercise 1.d. Can you think of more structure on the set of possible worlds? For example, a relation of closeness (or comparative similarity) as in the semantics for counterfactuals? Note your ideas and come back to them once we later have learned about the topology that can be put on the set of possible worlds (as hinted at in the text above). Compare this topology to your ideas.

Exercise 1.e. Can you think of more examples where a duality is involved? In cognitive science: what about concepts vs. mental states (computable theory of mind vs **connectionism**). Or, related, in AI: or human-interpretable concepts (symbolic) vs. states of neural networks (subsymbolic)?

Exercise 1.f. Go through the discussed examples of duality again and think about where they should be made philosophically and/or mathematically more precise.

2 The algebraic side: distributive lattices

This chapter introduces formally the algebraic side of duality, which, for us, will be distributive lattices. They are particular partial orders. So, in section 2.1, we first recall order theory (which is very useful in general). Then, in section 2.2, we define lattices as particular partial orders, and we give an equivalent definition which is more algebraic (i.e., in terms of operations that satisfy equations). In section 2.3, we define when lattices are distributive and when they even are Boolean algebras. And we end with section 2.4, where we already establish a duality between finite sets (resp. finite partial orders) on the one hand and finite Boolean algebras (resp. finite distributive lattices) on the other hand. This will provide a good idea of the more general case of Stone (resp. Priestley) duality. The main missing ingredient for the general case is topology, which will be the topic of the next chapter.

2.1 Order theory

The objects that order theory studies are known as partial orders. We define them in section 2.1.1. The ‘structure-preserving’ maps between partial orders are known as monotone maps. We define those, and variants thereof, in section 2.1.2.

We follow one of the keys lessons of category theory: that one not only should specify the class of objects that one studies but also the class of appropriate maps—which are called morphisms—between them. These two data then constitute a category, provided some basic axioms are satisfied (that morphisms can be composed and that there is the identity morphism). We will introduce basic notions from category theory later when we need them. For now we only foreshadow it with the ‘objects’ and ‘morphisms’ distinction.

Probably we add an extra chapter on it. If so, link to it here.

2.1.1 Objects: Partial orders

Partial orders occur everywhere: when you have a bunch of things where it makes sense to say that some are bigger (better, higher, etc.) than others. The things could be numbers with the usual sense of being bigger than.

But the things could also be the dishes offered at your go-to lunch place with the sense of ‘better’ given by your preferences. The formal definition goes as follows.

Definition 2.1. A *partial order* (or *partially ordered set*, or *poset*) is a pair (P, \leq) where P is a (possibly empty) set and \leq is a binary relation on P such that

1. *Reflexive*: For all $a \in P$, we have $a \leq a$.
2. *Transitive*: For all $a, b, c \in P$, if $a \leq b$ and $b \leq c$, then $a \leq c$.
3. *Anti-symmetric*: For all $a, b \in P$, if $a \leq b$ and $b \leq a$, then $a = b$.

If we do not require axiom 3, we speak of a *preorder*. We say \leq is a (partial or pre-) order on P . If the order \leq is clear from context, we often simply speak of the (partial or pre-) order P .

The name ‘partial’ is to indicate that not all elements need to be comparable: Formally, for $a, b \in P$, we say that a and b are *comparable*, if either $a \leq b$ or $b \leq a$; otherwise they are *incomparable*. If all elements are comparable, we say (P, \leq) is a *linear* (or *total*).

Formally, the example of the numbers is (\mathbb{N}, \leq) where \mathbb{N} is the set $\{0, 1, 2, \dots\}$ and, for $n, m \in \mathbb{N}$, the relation $n \leq m$ is defined as: n is smaller or equal to m (equivalently, there is $k \in \mathbb{N}$ such that $n + k = m$). Hence this is a linear order. In the example of your lunch place, if you have two dishes a and b that you find equally tasty—or, more precisely, none tastier than the other, i.e., a and b are incomparable—, then your preference order is only partial and not linear.

There is a nice visualization of partial orders. They are known as Hasse diagrams. An example is in figure 2.1. It depicts the partial order (P, \leq) with $P = \{a, b, c, d\}$ and

$$\leq := \{(a, a), (a, b), (a, c), (a, d), (b, b), (b, d), (c, c), (c, d), (d, d)\}.$$

This definition of the order is not particularly enlightening, but the diagram is. Its nodes are the elements of P and the edges are the minimal information to recover the order:

- if there is an edge between x and y and x is lower (on the page) than y , then $x \leq y$.
- we do not need to draw an edge from one node to itself because for all nodes x we have $x \leq x$.

A binary relation R on a set P is simply a subset of $P \times P = \{(a, b) : a, b \in P\}$. For $a, b \in P$, one writes aRb for $(a, b) \in R$.

Check that this satisfies the axioms.

Figure 2.1: The ‘diamond’ as an example of a partial order.

- we do not need to draw edges that result from composing existing edges: for example, we have an edge from a to b and an edge from b to d , so we already know that $a \leq d$, hence we do not need to draw this.

More formally, the definition of a Hasse diagram of a partial order (P, \leq) is as follows. For $a, b \in P$, we say that b *covers* a (short $a < b$) if $a \leq b$ and for all $c \in P$, if $a \leq c \leq b$, then $c = a$ or $c = b$. The elements of P are the nodes of the Hasse diagram, and an edge is drawn from node a to node b whenever b covers a . The direction of the edge is indicated by drawing b higher up in the diagram than a . So nodes on the same height are incomparable.

Next, some very useful concepts to talk about partial orders are the following.

Definition 2.2. Let (P, \leq) be a partial order and $A \subseteq P$.

- An element $b \in P$ is a *lower bound* of A if, for all $a \in A$, we have $b \leq a$.
- An element $b \in P$ is an *upper bound* of A if, for all $a \in A$, we have $a \leq b$.
- An element $c \in P$ is an *infimum* or *greatest lower bound* of A if (1) c is a lower bound of A , and (2), for all lower bounds b of A , we have $b \leq c$.
- An element $c \in P$ is a *supremum* or *least upper bound* of A if (1) c is an upper bound of A , and (2), for all upper bounds b of A , we have $c \leq b$.
- An element $b \in P$ is a *least* or *bottom* or *minimum* element of P , if, for all $a \in P$, we have $b \leq a$ (i.e., b is the supremum of $A = \emptyset$).

They can be confusing at first, but they really are worth learning. Make sure to draw little Hasse diagrams to illustrate the concepts and how they differ from each other.

- An element $b \in P$ is a *greatest* or *top* or *maximum* element of P , if, for all $a \in P$, we have $a \leq b$ (i.e., b is the infimum of $A = \emptyset$).
- An element $b \in P$ is *minimal* if, for all $a \in P$, if $a \leq b$, then $a = b$.
- An element $b \in P$ is *maximal* if, for all $a \in P$, if $b \leq a$, then $b = a$.
- An element $b \in P$ is *minimal in A* if (1) $b \in A$ and (2) for all $a \in A$, if $a \leq b$, then $a = b$.
- An element $b \in P$ is *maximal in A* if (1) $b \in A$ and (2) for all $a \in A$, if $b \leq a$, then $b = a$.

(These notions also make sense in a preorder (P, \leq) , but if P is a partial order, then infimum and supremum are unique if they exist.) The infimum is denoted $\bigwedge A$, called the *meet* of A ; and the supremum is denoted $\bigvee A$, called the *join* of A . If $A = \{a_1, \dots, a_n\}$ is finite and nonempty, we write $\bigwedge A = a_1 \wedge \dots \wedge a_n$ and $\bigvee A = a_1 \vee \dots \vee a_n$. In particular, $\bigwedge \{a, b\} = a \wedge b$ and $\bigvee \{a, b\} = a \vee b$. The bottom element, if it exists, is denoted \perp or 0 ; and the top element by \top or 1 . We write $\min(A)$ (resp. $\max(A)$) for the elements that are minimal (resp. maximal) in A .

Finally, one useful operation on preorders is that we can ‘turn them upside down’ and get another preorder. Formally, if (P, \leq) is a preorder, define the preorder \leq' on P by $a \leq' b$ iff $b \leq a$. We write P^{op} for this preorder.

2.1.2 Morphisms: Monotone maps

What maps between partial orders should be considered to be ‘structure preserving’? Surely they should preserve the order structure. This yields the concept of a monotone map, and is the standard choice. But there also are other ones, which we mention as well.

Definition 2.3. Let (P, \leq_P) and (Q, \leq_Q) be two preorders and $f : P \rightarrow Q$ a function. We say f is

- *monotone* or *order preserving* if, for all $a, b \in P$, if $a \leq_P b$, then $f(a) \leq_Q f(b)$.
- *order reflecting* if, for all $a, b \in P$, if $f(a) \leq_Q f(b)$, then $a \leq_P b$.
- an *order-embedding* if f is both order preserving and order reflecting.
- an *order-isomorphism* if f is a surjective order-embedding.

It is a good exercise to prove this.

Verify that this again is a preorder (resp. partial order), and draw some Hasse diagram example to see that this really turns things upside down.

We consider the words ‘map’ and ‘function’ as synonymous.

Order-embeddings between posets are injective, but the converse fails (i.e., there are injective order preserving maps between posets which are not order-embeddings).

An equivalent (and more category-theoretic) definition of an order-isomorphism is as a monotone map which has a monotone inverse. In full: A monotone function $f : P \rightarrow Q$ between two preorders is an order-isomorphism if there is a monotone function $g : Q \rightarrow P$ such that

- for all $a \in P$, we have $a = g(f(a))$ (i.e., $g \circ f = \text{id}_P$), and
- for all $b \in Q$, we have $b = f(g(b))$ (i.e., $f \circ g = \text{id}_Q$).

If two preorders are isomorphic (i.e., there is an order isomorphism between them), we can consider them to be essentially identical. This is difficult to achieve, so it makes sense to look for a *generalization* of the concept of an isomorphism. The key idea is to still require a monotone function $g : Q \rightarrow P$ in the other direction, but it need not be the *true* inverse but only the best possible *approximation* to an inverse:

- for all $a \in P$, we have $a \leq_P g(f(a))$, and
- for all $b \in Q$, we have $b \leq_Q f(g(b))$.

Another way of defining this is as follows (it is an exercise to show that this is indeed equivalent).

Definition 2.4. Let (P, \leq_P) and (Q, \leq_Q) be preorders, and let $f : P \rightarrow Q$ and $g : Q \rightarrow P$ be monotone functions. The pair (f, g) is called an *adjunction*, with f the *left* or *lower adjoint* and g the *right* or *upper adjoint*, if, for all $a \in P$ and $b \in Q$,

$$f(a) \leq_Q b \text{ iff } a \leq_P g(b).$$

An adjunction between P^{op} and Q is called a *Galois connection* or *contravariant adjunction*.

It is best to illustrate this abstract concept with examples. An important template of how Galois connections arise is the following (which includes the instance coining them).

Lemma 2.5. Let $R \subseteq X \times Y$ be a relation between two sets. For any $a \subseteq X$ and $b \subseteq Y$, define

$$u(a) := \{y \in Y : \forall x \in a. xRy\} \subseteq Y$$

$$l(b) := \{x \in X : \forall y \in b. xRy\} \subseteq X$$

Then $u : \mathcal{P}(X) \rightarrow \mathcal{P}(Y)$ and $l : \mathcal{P}(Y) \rightarrow \mathcal{P}(X)$ for a Galois connection between the posets $(\mathcal{P}(X), \subseteq)$ and $(\mathcal{P}(Y), \subseteq)$, i.e., for any $a \subseteq X$ and $b \subseteq Y$, we have $b \subseteq u(a)$ iff $a \subseteq l(b)$.

Here id_X denotes the identity function on set X . And if $f : X \rightarrow Y$ and $g : Y \rightarrow Z$ are functions, $g \circ f$ (g after f) denotes their composition, which maps $x \in X$ to $g(f(x)) \in Z$.

This is an advanced concept. Give yourself the time to let it sink in by coming back to it over and over again.

Note that f occurs on the left of ' \leq ' and g on the right.

Here $\mathcal{P}(X)$ is the set of all subsets of the set X .

Here are three instances.

1. Maybe you know the name 'Galois' from the theory of fields in algebra. Then you know **Galois theory** as relating fields to groups. This connection arises via the above lemma from the relation R between the set X of subfields of a given field and the set Y of automorphisms of this field, which relates a subfield to the automorphisms which are the identity on this subfield.
2. If X is a set and $R \subseteq X \times X$ is a preorder, then $u(a)$ is the set of upper bounds of $a \subseteq X$, and $l(b)$ is the set of lower bounds of $b \subseteq X$.
3. Consider a class of structures \mathcal{C} (in, say, a first-order signature) and a class \mathcal{F} of formulas (of this signature). Let \models be the *interpretation* relation: For $M \in \mathcal{C}$ and $\varphi \in \mathcal{F}$ means that structure M makes true formula φ . Then for a set of models a , $u(a)$ is the theory of a , i.e., the set of formulas that are true in all those models. And for a theory $b \subseteq \mathcal{F}$, $l(b)$ is the class of models of b , i.e., the set of models which make true all the sentences in b .

But you don't need to know this for the course.

Also recall the examples from section 1.1.

2.2 Lattices

2.3 Distributive lattices and Boolean algebras

2.4 Duality for finite distributive lattices and finite Boolean algebras

3 The spatial side: topological spaces

4 Two sides of the same coin: Priestley and Stone duality
